Abstract

How scientific ideas are communicated can shape how they are evaluated, disseminated, and ultimately integrated into cumulative knowledge. This paper studies whether author-team gender composition is associated with differences in scientific writing in economics. Using 9,117 abstracts from top general-interest economics journals and a 16-item LLM-based rubric, we first benchmark the LLM readability measure against Hengel's established readability metrics. We then examine mean differences across writing dimensions and estimate regressions with extensive journal, year, article, and author controls. Female-majority teams write more readable, less jargon-heavy, and more direct abstracts, and they generally provide more evidentiary support. They also make weaker novelty claims. By contrast, differences in hedging, qualifiers, assertiveness, and emotional valence are small or inconsistent.

Extending the analysis to peer review, we find that, unlike Hengel's readability measure, LLM readability shows no differential gender effect from the review process. In cumulative-exposure tests, the aggregate preemptive-adaptation pattern Hengel documents for readability is largely absent for LLM scores, though patterns resembling that mechanism appear in three specific dimensions: acknowledgement of limitations, modal verb strength, and novelty-claim strength. We read these dimension-specific patterns as suggestive rather than definitive, since evaluation noise and the limited granularity of the LLM rubric remain plausible contributors.

Keywords: Gender differences; scientific writing; readability; natural language processing; team composition.

JEL Classification: J16; C55; C81.

1 Introduction

Scientific writing is not a neutral container for ideas. The way results are framed, in particular, how directly arguments are stated, how much jargon is used, whether evidence is foregrounded, and how strongly novelty is claimed, can shape both peer evaluation and the dissemination of knowledge. This possibility echoes a broader concern, associated with the idea of a "different voice" (Gilligan 1993), that dominant evaluative standards may overlook systematically different modes of communication. Yet empirical work in economics has focused much more on gender differences in publication, promotion, and review outcomes than on the writing itself.

This paper asks whether the gender composition of author teams is associated with systematic differences in how economists write. The paper builds most directly on Hengel 2022, who shows that female-authored papers are more readable and appear to face higher writing standards in peer review. We extend that insight beyond readability by measuring a broader set of surface-level writing features in abstracts, including directness, jargon, evidence and citation usage, active voice, novelty claims, hedging, and related rhetorical dimensions. The objective is not to infer author intent or personality from text. Rather, it is to identify whether different teams systematically present research in different ways.

Our data comes from Hengel 2022, with the main analysis conducted on 9,117 abstracts from four top general-interest economics journals between 1950 and 2015. Each abstract is evaluated using a 16-item LLM-based rubric covering readability, technicality, directness, evidentiary support, and rhetorical style. Because LLM-based measures may invite skepticism, the empirical analysis proceeds in several steps. First, we benchmark the LLM readability score against the readability measures used in Hengel 2022. Second, we examine unconditional mean differences across all 16 criteria. Third, we estimate regressions that add journal, year, article, and author controls to assess whether the observed patterns persist after accounting for observable compositional differences. Finally, we extend the analysis to peer review, testing both whether peer review differentially affects writing by author gender and whether any such differential erodes as female authors accumulate publishing experience.

The validation exercise shows that the LLM readability measure tracks the same underlying pattern documented by Hengel 2022. In unconditional comparisons, female-majority teams score higher on readability, directness, accessibility of language, and evidence/citation usage, and they make weaker novelty claims. Once controls are added, the clearest differences remain higher readability, less jargon, greater directness, more evidentiary support, and weaker novelty claims among female-majority teams. By contrast, differences in assertiveness, qualifiers, emotional valence, and several other tonal dimensions are small or unstable across specifications. The results, therefore, do not support a simple story in which women write in a uniformly more hesitant or emotional way. The clearest differences are concentrated instead in clarity, technical density, and the organization of claims.

We then extend this analysis to how the differences evolve during peer review and with cumulative publishing experience. Here, we show that while peer review measurably affects LLM-evaluated writing quality on average, it does so similarly for male- and female-authored papers, in contrast to the differential effect Hengel 2022 document for readability. In tests of cumulative exposure, the aggregate "preemptive adaptation" pattern Hengel identifies (in which experienced female authors increasingly produce cleaner drafts rather than relying on review to close the gap) is largely absent at the composite level of LLM scores. Patterns resembling that mechanism do, however, resurface in three specific dimensions. Acknowledgement of limitations and modal verb strength both exhibit a pattern resembling the preemptive-adaptation signature, which would be consistent with female authors learning and internalizing reviewer expectations over time. Novelty-claim strength instead shows a distinct pattern in which peer review consistently dampens female authors' novelty framing across all experience levels; one reading of this is persistent reviewer resistance rather than rational adaptation. We emphasize that these dimension-specific readings are suggestive, not definitive: evaluation noise and the limited granularity of the 1 to 10 rubric remain plausible contributors to the observed patterns.

This paper contributes to three literatures. First, it adds to work on gender and evaluation in economics by studying writing style as a potential input into evaluation rather than focusing only on publication or career outcomes. Second, it extends readability analysis from Hengel 2022 to a multidimensional measurement framework that separates clarity and structure from tone and affect. Third, by showing which dimensions move together with team gender composition and which do not, and where the peer-review mechanism Hengel documents is and is not visible, it sharpens the debate over what a "different voice" in economics actually consists of and where differential review pressure may bind most tightly.

The remainder of the paper proceeds as follows. Section 2 reviews the related literature. Section 3 describes the data, authorship measures, and LLM rubric. Section 4 outlines the empirical strategy. Section 5 presents the validation exercise, mean-difference analysis, and controlled regressions. Section 6 concludes.

2 Related Literature

This paper sits at the intersection of two literatures.[1] The first concerns gender, voice, and communication. Gilligan 1993 provides the motivating intuition that dominant evaluative frameworks may overlook alternative ways of presenting judgment and reasoning. Although that literature is not about economics articles specifically, it suggests that apparently neutral standards of professional communication may embed preferences for particular styles of exposition.

The second is the economics literature on gender and the production and evaluation of research. Card et al. 2020 study whether referees and editors in economics treat submissions differently by gender, and Sarsons 2017 shows that collaborative work can be differentially recognized by gender. Most directly, Hengel 2022 documents that female-authored economics papers are more readable and that the writing gap widens during peer review, consistent with women facing higher writing standards in publication.

This paper contributes to that literature in three ways. First, rather than studying

1. **This paper is a work in progress intended solely for feedback and should not be circulated.**

editorial decisions, citations, or promotion outcomes, we focus on writing itself as an observable input into evaluation. Second, we move beyond a single readability measure by using a multidimensional rubric that distinguishes clarity and structure from tone, assertiveness, and affect. This matters because several common narratives about gendered writing, such as those centered on hedging, confidence, and emotionality, receive limited support in our data. Third, by organizing the evidence in three steps, validation of the LLM measure, unconditional mean differences, and controlled regressions, we show both that the measurement is anchored to existing work and that the main patterns are not driven solely by compositional differences across journals, years, or paper types.

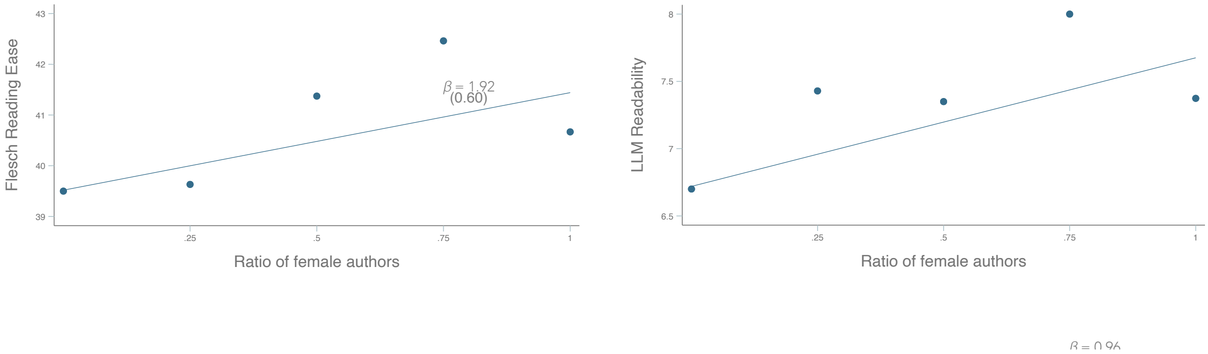
3 Data and Measurement

The data used for this paper are drawn from the publicly available replication package for Hengel 2022, hosted on GitHub. The data package covers 11695 English-language articles from the years 1950 to 2015 from 5 top journals in economics: American Economic Review (AER), Quarterly Journal of Economics (QJE), Econometrica (ECMA), Review of Economic Studies (ReSTUD), and Journal of Political Economy (JPE). The majority of the analysis in this paper excludes ReSTUD, which Hengel 2022 includes primarily for its availability of submission-acceptance dates, and AER Papers & Proceedings, which do not contain abstracts. A full breakdown of articles by journal and decade is in Appendix B.

The article data includes the title, abstract, citation count, submission and acceptance date, JEL codes, and pre-computed readability scores from Hengel 2022. The article data is linked with author-level data on gender, native language, and institution.

For this paper, we do not re-estimate readability scores or re-verify the gender coding of Hengel 2022. We also exclude any analysis of full-text readability, as processing the full text through the LLM would be prohibitively expensive at scale and because evaluation quality degrades with longer inputs (Modarressi et al. 2025).

Following Hengel 2022, our main specification classifies papers as 'male-authored' when women constitute a strict minority of the author team. For papers where women are a majority, the gender variable is defined as the ratio of female to male authors.



(a) Flesch Readability

(b) LLM Readability

Figure 1: Relationship between readability and the ratio of female authors

Figure 1 plots readability against the female author ratio for two measures: Flesch readability (copied from Hengel 2022) and LLM readability. Although they both show a broadly positive relationship, they differ in shape. For robustness, we therefore also estimate our main results under alternative authorship specifications:

- Using a binary equal to 1 if the article's authors are majority female
- Using a binary equal to 1 if there is 1 female coauthor
- Using only single-gender papers
- Using only solo-authored articles
- Comparing articles with a senior female coauthor to entirely male-authored papers

Further description of the data can be found in Section 2 and Appendices C and D of Hengel 2022.

3.1 Tonal Analysis Rubric

Additionally, we use a 16-item rubric to evaluate paper abstracts on the scale of 1-10 for Modal Verb Strength, Hedging Frequency and Type, Qualifier Density, Acknowledgment of Limitations, Caution-Signaling Connectors, Assertiveness and Voice, Active/Passive

Voice Ratio, Sentence Length and Directness, Imperative-Form Occurrence, Pronoun Commitment, Novelty-Claim Strength, Jargon and Technicality Density, Emotional Valence, Evidence and Citation Usage, Practical and Impact Orientation, Readability. See exact evaluation rubric in Appendix: Rubric.

3.2 LLM Evaluations

To conduct the tonal evaluations, we developed a Large Language Model (LLM) powered algorithm that would take the abstracts from the papers, process them into a readable LLM message, and then pass the message through to the LLM, which would, in turn, provide a structured output of evaluations. The LLM model we chose for this analysis was GPT-5, which includes both standard LLM capabilities and the ability for more complex reasoning. We valued the model's ability to generate detailed thinking processes before answering to handle the complexity of our multi-dimensional tonal analysis rubric, as reasoning models have performed better than non-reasoning models as task complexity increases (Shojaee et al. 2025). This also allowed us to keep our input token count to a minimum, which increases model accuracy (Modarressi et al. 2025).

This process of passing the abstracts and rubric to the model is sufficient to generate the needed evaluations, but insufficient in providing the most accurate responses. To increase response accuracy, we implemented prompt engineering, a process of creating clear instructions for the model to increase performance (OpenAI 2025). Part of this process is to induce step-by-step thinking in the model and allow for model reasoning for each section of the rubric, both shown to increase model accuracy (Zhang et al. 2022).

To validate the accuracy of the evaluations, we first trained the algorithm on a small subset of abstracts, auditing the evaluation output and reasoning for these responses and using that to improve our prompt. We then tested the algorithm on a different subset of abstracts to validate the output and reasoning before running the algorithm on the full dataset. A separate validation was performed using readability scores, comparing our outputs against Hengel (2022) manually calculated readability scores, checking to see if our evaluations were consistent with hers at the population level.

Despite the validation involved with calibrating the LLM for our project, there is still some randomness involved in the LLM evaluations. Because of this, the standard errors for analysis using LLM evaluations do not fully reflect the instability of our estimates.

4 Empirical Methodology

Our empirical analysis proceeds in four steps. First, we validate the LLM-based readability score by benchmarking it against the readability measures used in Hengel 2022. This shows that the LLM measure is anchored to an existing and interpretable construct rather than being an arbitrary score. Second, we present unconditional mean differences across the 16 standardized writing-style criteria. Third, we estimate regressions that add journal, year, article, and author controls to assess whether the observed differences survive after accounting for observable compositional differences across papers and teams. Finally, following Hengel 2022, we extend our analysis to examine the differences that arise in peer review and as experience is gained. Before we present our formal analysis, we describe summary statistics of our data.

4.1 Summary Statistics

In total, across the top 4 journals, we have 9117 articles, written by 16055 authors, of whom fewer than 10% are women. Out of all articles, 8264 are single gender out of which only about 3% are female-only articles. About 13% of articles have at least 1 female author, and 9% have a majority of female authors.

Table 7 in Appendix B gives the mean and standard deviations for the LLM evaluations of every rubric item. This table also clearly shows the outlines of a gender writing difference, with Readability, Sentence Length, and Directness, and Acknowledgment of Limitations showing large differences in means between the all-male and all-female populations. Further summary statistics are available in Appendix B.

4.2 Analysis

Hengel 2022 establishes three main empirical findings: that female-authored papers are written more clearly than comparable male-authored papers; that this gap widens during peer review, suggesting women face higher standards from referees; and that female authors who are more exposed to the review process show larger improvements in writing quality over time. We replicate and extend each of these analyses by substituting our LLM-based writing quality measure for the original readability indices. The subsections below describe the empirical approach for each.

4.2.1 Gender Differences in Writing Quality

To estimate the relationship between author gender and writing quality, we regress readability scores on the female authorship measure, controlling for various article- and author-level variables, using different specifications. The estimating equation is:

$$R_j = \beta_0 + \beta_1 \textit{female ratio}_j + \gamma \mathbf{X}_j + \delta \mathbf{Y}_j + \varepsilon_j \tag{1}$$

where R_j is the readability score for article j, $\textit{female ratio}_j$ is the female authorship measure described in Section 3, $\mathbf{X}_j$ is a vector of article-level controls, $\mathbf{Y}_j$ is a vector of author-level controls, and β_1 is the coefficient of interest. To the original analysis, we add our readability score and the rubric's tonal criteria group composite scores as dependent variables. For a full discussion of identification, see Hengel 2022 Section 3.2.

4.2.2 The Effect of Peer Review

To estimate the effect that peer review has on readability by gender, we estimate two different models. The first is a first difference model, whose estimating equation is given by:

$$R_j^P - R_j^W = \beta_0^P + \beta_1^P \textit{female ratio}_j + \theta^P \mathbf{X}_j^P + \mu_j^P + \varepsilon_j^P \tag{2}$$

where R_j^P and R_j^W are readability scores for the published and working paper versions of article j, respectively, $\mathbf{X}_j^P$ is a vector of published-version-specific controls, μ_j^P captures unobservable factors, and β_1^P captures the impact of female authorship on the change in readability that occurs specifically during peer review. For β_1^P to be causal, there must be zero partial correlation between β_1^P and μ_j^P.

The second model Hengel 2022 estimates is a feasible generalized least squares model (FGLS) based on Ashenfelter and Krueger 1994. The reduced-form equations are:

$$R_j^W = \tilde{\beta}_0^W + \tilde{\beta}_1^W \, \textit{female ratio}_j + \tilde{\theta}^W \mathbf{X}_j^W + \delta^P \mathbf{X}_j^P + \tilde{\varepsilon}_j^W \tag{3}$$

$$R_j^P = (\tilde{\beta}_0^W + \beta_0^P) + (\tilde{\beta}_1^W + \beta_1^P) \, \textit{female ratio}_j + \tilde{\theta}^W \mathbf{X}_j^W + \tilde{\theta}^P \mathbf{X}_j^P + \mu_j^P + \tilde{\varepsilon}_j^P \tag{4}$$

where the tilde terms absorb the correlation between version-invariant unobservables and the observable controls. β_1^P is identified post-estimation by subtracting the coefficient on $\textit{female ratio}_j$ in Equation (3) from that in Equation (4).

We estimate these models with 2 data samples. The first is the full subset of 1988 articles for which we have NBER working papers. The second is with a subset of AER and QJE articles that underwent blind review. For the full derivation, see Hengel 2022, Section 3.3.

4.2.3 Cumulative Exposure to Peer Review

The gender readability gap documented in the above subsections could be driven by two broad mechanisms. The first is internal factors: women may voluntarily write more clearly due to, for example, higher risk aversion, lower confidence, or a greater tendency to exert effort on tasks without obvious returns (Croson and Gneezy 2009, Coffman 2014, Babcock et al. 2017). The second is external factors: women may write more clearly as a rational response to higher standards imposed by referees and editors.

These two mechanisms generate distinct predictions about how the readability gap should evolve as authors gain experience in peer review. If internal factors dominate, the gap should shrink over time, as women would gradually learn that they are exceeding the standards required for publication and reduce their effort accordingly. If external factors dominate, the gap should grow. Women would initially underestimate the bar they are held to, but revise their beliefs upward as they accumulate experience with the review process. The source of the gap should also shift: in early publications, the gap should emerge primarily during peer review, as referees and editors push female authors to revise more heavily. In later publications, the gap should emerge primarily before peer review, as women anticipate higher standards and submit better-written drafts from the beginning.

Following Hengel 2022, we test for the presence of external factors by examining how readability changes across authors' successive publications. Specifically, we estimate whether the coefficient on female authorship grows with publication order, which would be consistent with women learning about and adapting to higher standards over time. We note that the interpretation of this analysis as evidence of external factors requires the additional assumption that women are not rewarded for their better writing with higher acceptance rates, something we cannot test directly but is supported by evidence from Card et al. 2020 showing that female-authored papers are not accepted more frequently than comparable male-authored papers at a similar set of journals.

To implement this test, we estimate the following equation separately for working papers ($m = W$) and published articles ($m = P$):

$$R_{itm} = \beta_0 + \beta_1 \text{female ratio}_{it} + \beta_2 \text{female ratio}_{it} \times t_{it} + \beta_3 t_{it} + \theta X_{it} + \varepsilon_{it}, \tag{5}$$

where R_{itm} is the readability or LLM score for author i's tth top-four paper in version m, t_{it} is author i's cumulative number of top-four publications, and X_{it} is a vector of controls. The coefficient β_1 captures the baseline gender gap at an author's first publication, while β_2 captures how that gap evolves with experience. A positive and significant β_2 in the working paper specification would indicate that women submit progressively better-written drafts as they accumulate peer review experience, consistent with a preemptive response to higher standards. A positive β_2 in the published paper specification that exceeds its working paper counterpart would additionally suggest a direct effect operating through the review process itself.

5 Results

5.1 Gender Difference in Writing Quality

5.1.1 Benchmarking the LLM Readability Measure

We start by using the LLM readability score to make a comparison with Hengel 2022. Table 1 shows the results of regressing various readability scores on the ratio of female authors. The first 5 rows of Table 1 replicate the corresponding specifications from Hengel 2022. The final row adds the LLM readability score as the dependent variable.

Results for Table 1 suggest that abstracts written by women score between 0.27 and 0.4 points higher on average on our rubric than those written by men after accounting for different levels of controls. The estimates are significant at the one percent level for all levels of controls, though this does not fully account for possible inconsistencies or noise in the LLM evaluation process, meaning the true standard errors are likely higher.

Appendix C.1 shows Table 1 estimated using the alternative specifications for female authorship described in Section 3. These alternative specifications yield similar coefficients and statistically significant results for the LLM readability metric, indicating robustness.

5.1.2 Mean Differences in Writing Style

After establishing the consistency of LLM-based readability scores with manually defined readability scores from Hengel 2022, we look at other tonal criteria. We start by comparing sample means for male and female authors for each of the 16 rubric items. To define the gender of a paper, we use the gender of the majority of the authors. That is, if at least 50% are female, we call the paper female-authored and male otherwise. For better comparison across rubric items, we standardized all criteria with mean and standard deviation. Figure 2 shows the difference in means with 95% intervals for each of the 16 standardized criteria.

Notes. Figures represent coefficients on female ratio from 45 separate OLS regressions of readability scores on the ratio of female authors (papers with fewer than 50 percent female authors are classified as male, see the text). (6)–(9) are estimated on the sample of papers published on or after 1990 with a primary *JEL* code; (9) includes 563 articles from *AER P&P* (see the paper). Quality controls denoted by ✓^{1} include citation count (asinh), max. T fixed effects (author prominence) and max. t (author seniority). Standard errors clustered on editor in parentheses. ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

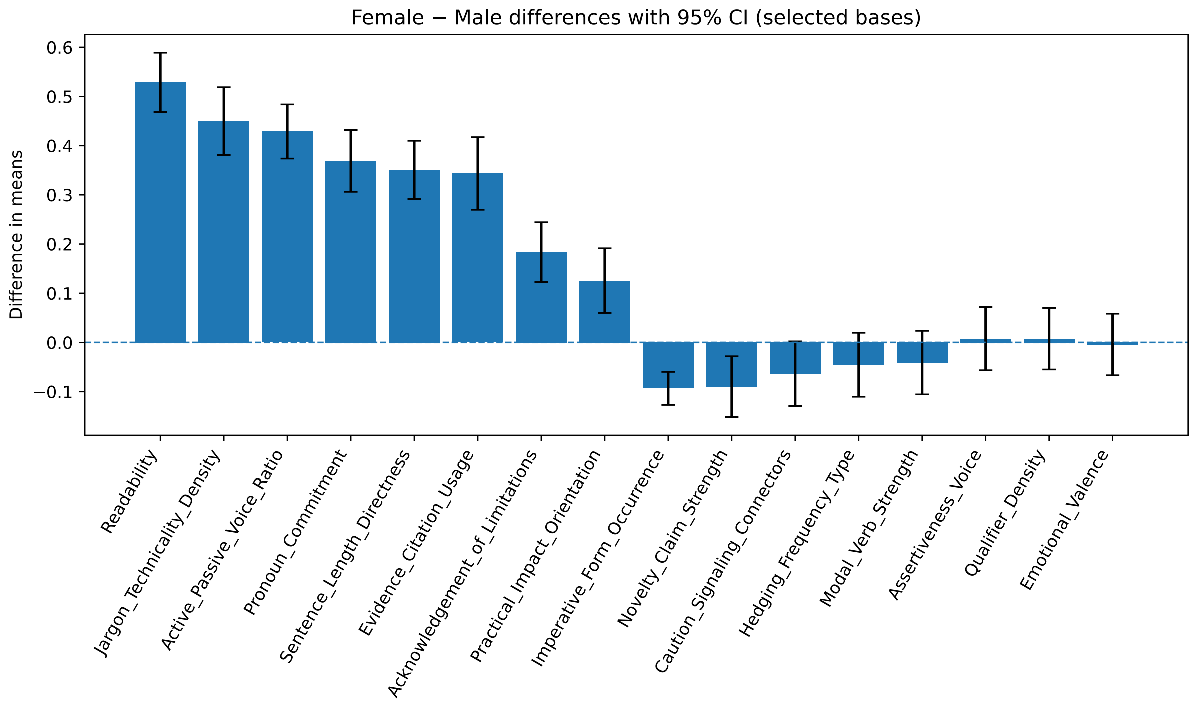

Figure 2: Papers are classified as female if at least 50% of authors are female, and male otherwise. All criteria are standardized (mean zero, unit standard deviation) for comparability. Figure shows differences in means with 95% confidence intervals across the 16 criteria. The sign of "Jargon Technical Density" is reversed so that positive values indicate less jargon for female-majority papers; for all other criteria, positive values indicate higher scores for females.

Taken together, the evidence points to systematic and robust differences in writing by team gender composition. Female-majority teams emphasize clarity – higher readability and greater directness – use more active voice, avoid jargon, and provide more evidentiary support through citations. Differences in acknowledgment of limitations are statistically significant but modest in magnitude; under our coding, positive values indicate that female-majority teams make fewer explicit limitation statements (see Appendix A for the scale). There is also a smaller but significant tendency for female-majority teams to place greater emphasis on practical importance.

In contrast, differences in tone – such as assertiveness, qualifiers, hedging, and emotional valence – are generally small or negligible, with the exception of slightly weaker novelty claims and fewer imperatives among female-majority teams.

5.1.3 Controlled Regressions.

It is possible that the mean differences are simply due to Female or Male groups working on different types of research. To control for such compounding, we control for journal, publication year, and article characteristics.

Tables 21 and 22 in appendix C.3 show results. The full sample (columns 1 to 5) shows that there are statistically significant positive (female higher) differences in Sentence length, technical jargon, Evidence/citation usage, and readability, while there is a significant negative (female lower) difference in novelty claims.

5.2 The Effect of Peer Review

We continue our analysis by investigating whether the LLM scores show any signs of discriminatory bias that the Hengel 2022 scores show, first by looking at readability and extending to other criteria.

Table 2, estimates the two equations described in Section 4.2.2. Our coefficients of interest are in column 4 for the first-difference model and in column 10 for the FGLS model. The first 5 rows are exact replications of Table 5 in Hengel 2022, with the final row adding LLM readability to the analysis. This table clearly shows significant differential effects of peer review on the Hengel 2022 readability scores, but no significant differential effects on the LLM readability score. This is also true for blind-review estimates, where the original estimates show negative (though insignificant) differential effects, while the LLM readability coefficient changes very little.

Table 2: The impact of peer review on the gender readability gap

	OLS (score)			OLS (Δ in score)		FGLS (score)					
						Working paper		Published paper		Difference

Notes. Panel one displays coefficients from estimating equation (2) directly via OLS; standard errors clustered by editor in parentheses. Panel two displays coefficients from OLS estimation of equation (3); standard errors clustered by year in parentheses. Panel three displays coefficients from FGLS estimation of equation (6) and equation (7); standard errors clustered by year and robust to cross-model correlation in parentheses. Quality controls denoted by ✓^{2} include citation count (asinh), max. T (author prominence) and max. t (author seniority). The variable "female ratio" defines papers with a strict minority of female authors as male-authored; for papers with 50 percent or more female authors, it is the ratio of female authors on a paper (see the text for more details). ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

OLS (Δ in score) uses the change in LLM criterion score (published minus working paper) as the dependent variable; standard errors clustered by editor. FGLS (Difference) shows the published-minus-working-paper contrast from the FGLS model. †Jargon/Technicality Density is scale-flipped before analysis (raw 10 = dense jargon → stored as 1). ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

Tables 3 and 4, which estimate the same Section 4.2.2 equations but with individual LLM criterion scores, show similar results. Peer review raises scores on average (positive R_{jW} throughout), but the Female and Blind×female coefficients in both the OLS first-difference and FGLS difference columns are small and statistically insignificant across nearly all criteria, indicating no differential gender effect from the review process.

Appendix D presents estimates for Tables 2 and 3 under different female authorship specifications. The results shown here are robust to the different specifications, consistently showing no effect for the LLM evaluated criteria.

We propose 3 possible explanations for the absence of a differential gender effect in the LLM scores. The first is the possibility that the effect of peer review is drowned out by LLM evaluation noise, as the LLM may exhibit inconsistent evaluations from article to article. The second explanation is that the LLM rubric lacks sufficient granularity. The true effects documented in Hengel 2022 are on the order of a few percentage points, and a discrete 1–10 scale may not provide enough resolution to detect differences of that magnitude, particularly given our substantially smaller sample. The third is that the LLM evaluations capture a dimension of writing quality and style that is altogether different from the Hengel 2022 readability scores, something more internal to the author than externally imposed during review, and therefore unlikely to shift differentially by gender through the peer review process.

5.3 Cumulative Exposure to Peer Review

Now, we test the two broad mechanisms for the gender difference in readability described in Section 4.2.3. For this analysis, we will use the Flesch readability score to replicate the results of Hengel 2022, as well as the LLM readability score. For the individual criteria, we focus only on criteria shown in Figure 2 to have a significant difference between gender writing groups.

Table 5: Readability of authors' tth paper (draft and final)

	$t = 1$	$t = 2$	$t = 3$	$t = 4$–5	$t \geq 6$

Diff.-in-diff.	−0.01	−0.04	−0.07	−0.10	−0.14
	(0.11)	(0.10)	(0.10)	(0.12)	(0.14)

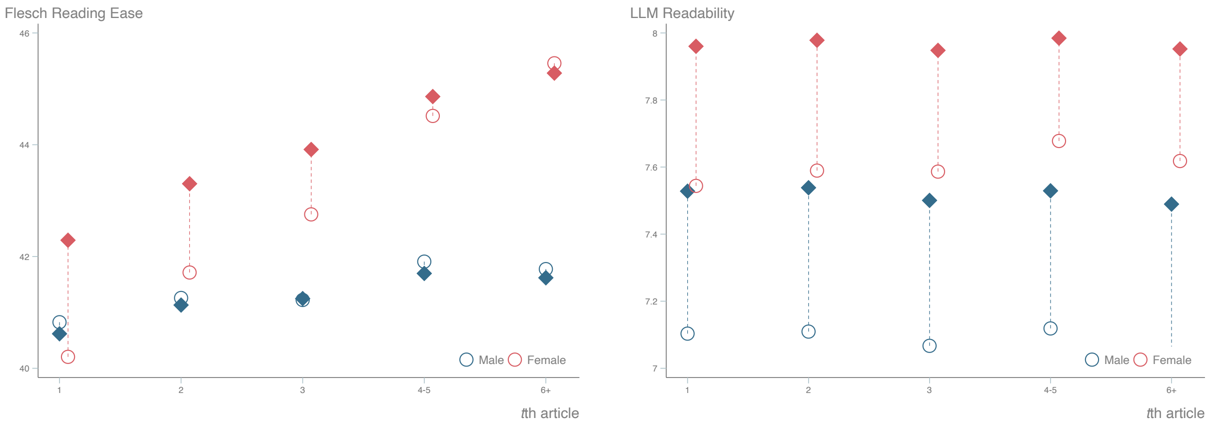
Notes. Sample 4,289 observations. Panel one displays magnitude of predicted $R_{jP} - R_{jW}$ (the direct effect of peer review) for women and men over increasing t. Panel two estimates the marginal effect of an article's female ratio ($\beta_1 + \beta_2 \times t$), separately for draft papers and published articles. Figures from FGLS estimation of equation (15), weighted by N_{it} (see the data appendix). Control variables include citation count (asinh), max. T (author prominence) and max. t (author seniority), native speaker and editor and journal-year fixed effects. Standard errors clustered by editor and robust to cross-model correlation in parentheses. ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

Table 5 estimates the equation found in Section 4.2.3 for two measures of writing quality: Flesch Reading Ease (Panel A) and LLM Readability (Panel B). The two panels tell strikingly different stories about how the gender gap in writing quality evolves with peer review experience.

Panel A replicates the key finding from Hengel 2022: the gender gap in published Flesch readability is relatively stable across publication counts, but its source shifts. At t=1, the gap forms almost entirely during peer review: women's papers improve by 2.09 points, while men's are essentially unchanged, producing a significant diff-in-diff of

2.29. By t≥6, the diff-in-diff has vanished, and the gap is instead driven by women submitting substantially more readable drafts (3.68 points higher than men's). This is the pattern predicted by the external-factors hypothesis: women learn about higher standards through experience and preemptively adapt.

Panel B shows no such pattern for the LLM score. In Panel B, peer review improves LLM readability by a similar, significant amount for both genders at every t, and the diff-in-diff is always near zero. The gender gap in drafts grows modestly with experience (from 0.44 to 0.60), but this is not accompanied by a corresponding decline in the direct effect of peer review — suggesting the improvement is internally driven rather than a response to review feedback.



(a) Flesch Readability (b) LLM Readability

Figure 3: Readability of Author's tth paper (draft and final)

Figure 3 shows the results of Table 5 in graphical form, where the differences are more striking. Figure 3a shows the readability gap shifting from coming entirely from the peer review process to women submitting better working papers. Figures 3b shows no such pattern, as the differences between the working paper and published paper readability score remain relatively constant through increasing t.

The remaining criteria — Hedging Frequency and Type, Sentence Length and Directness, Pronoun Commitment, Jargon/Technicality Density, and Evidence and Citation Usage — show the same pattern as LLM Readability: peer review effects that are relatively constant across experience levels with no meaningful gender differential. These are presented in Appendix G.1.

Three criteria, however, depart from this null result, producing patterns that resemble a rational behavioral response to external standards. We interpret these as suggestive rather than definitive, since, as discussed above, apparent departures could equally reflect LLM evaluation noise or the limited granularity of the 1 to 10 rubric rather than a genuine underlying mechanism.

Acknowledgement of Limitations. Figure 4 shows a pattern closely mirroring Figure 3a: the gap between working paper and published paper scores narrows with experience, while the gap between men and women widens. Female authors at low t receive significant upward revisions during peer review; by high t, this direct effect diminishes as women increasingly self-correct in the draft stage. This pattern is qualitatively consistent with the preemptive adaptation mechanism Hengel 2022 identify for readability, though given the limitations of the LLM measurement noted above, we cannot rule out that the apparent adaptive signature reflects measurement artifacts rather than a genuine behavioral response.

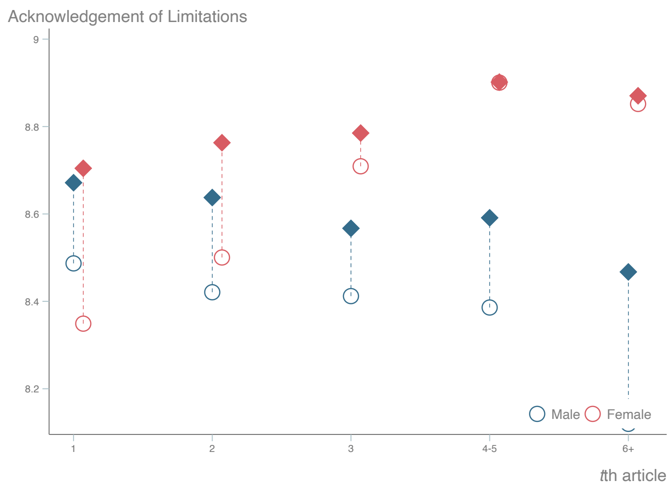


Figure 4: Acknowledgement of Limitations of Author's tth paper (draft and final).

Modal Verb Strength. Figure 5 shows a divergence between working and published papers that grows with experience: published papers trend upward in strong modal usage while working papers trend downward for female authors. One interpretation is that early in their careers, female authors learn that reviewers expect tentative language and preemptively soften their drafts, even as reviewer expectations themselves evolve over time. While this would be consistent with a response to external pressures, the divergence is modest and could alternatively reflect LLM scoring inconsistencies on a dimension (modal verb use) where the underlying signal is especially narrow and discretized.

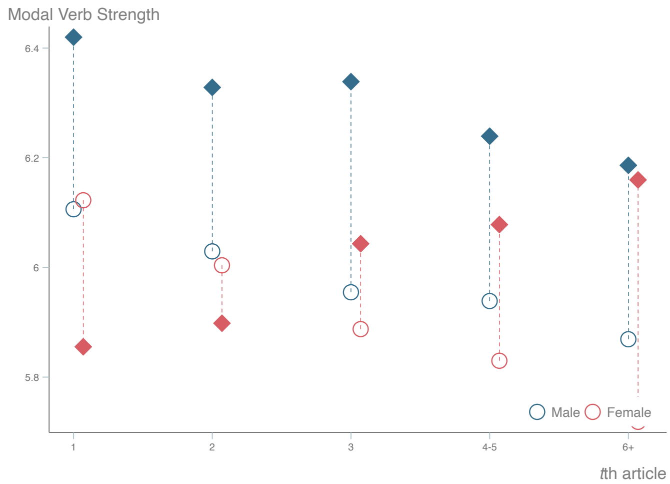

Figure 5: Modal Verb Strength of Author's tth paper (draft and final).

Novelty-Claim Strength. Figure 6 tells a qualitatively different story. Rather than preemptive softening, female authors appear to push back: working paper novelty claims increase steadily with t, as one could expect from a more senior economist growing in confidence. Yet published papers show a consistently lower novelty score across all experience levels. One reading of this is that peer review systematically dampens female authors' novelty framing regardless of seniority, a pattern less consistent with rational adaptation to known standards and more suggestive of persistent reviewer resistance to strong novelty claims from female authors. We emphasize that this is one possible interpretation: the same pattern is also consistent with LLM noise or with novelty being a dimension on which the LLM systematically captures something other than the review-relevant signal Hengel's readability measure captures.

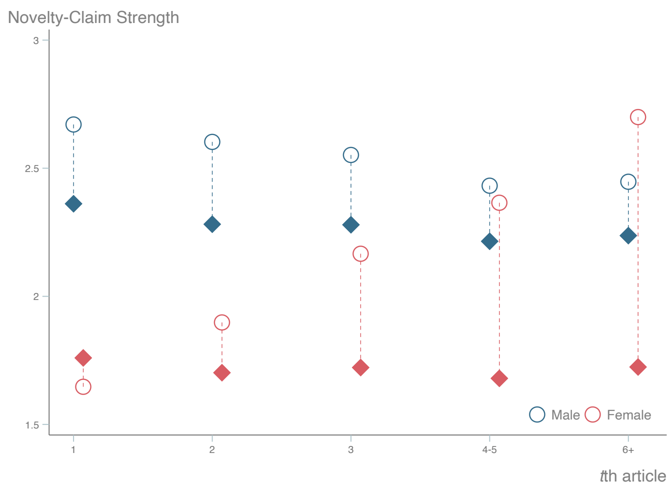

Figure 6: Novelty-Claim Strength of Author's tth paper (draft and final).

Taken together, the LLM-based measures show no aggregate evidence of the mechanism identified in Hengel 2022: across most criteria, there is no shift from a direct peer review effect to a preemptive adaptation effect as women gain experience. Instead, the LLM scores largely capture persistent features of writing style that evolve independently of the peer review process. Three exceptions stand out as the more suggestive findings: Acknowledgement of Limitations, Modal Verb Strength, and Novelty-Claim Strength. Each produces a pattern that could be read as a distinct mode of response to external standards, and together they raise the possibility that the mechanism Hengel identifies in readability is not entirely absent from LLM-evaluated writing but concentrated in specific dimensions of authorial stance and hedging. We caution, however, that all three of the alternative explanations for the aggregate null (evaluation noise, limited rubric granularity, and the LLM capturing a different underlying construct) apply equally to these dimension-specific patterns, and additional work is needed to distinguish a genuine mechanism from measurement artifacts.

6 Conclusion

This paper examines whether team gender composition is associated with systematic differences in how economists write. Using 9,117 abstracts and an LLM-based 16-item rubric, we first show that the LLM readability score aligns with established readability measures used by Hengel 2022. We then document broad mean differences in writing style across team gender composition and show, in controlled regressions, that several of these differences remain after accounting for journal, year, and a large set of article and author characteristics.

The most robust differences are not in emotionality or generalized lack of confidence. Instead, they are concentrated in clarity and presentation: female-majority teams write more readable and direct abstracts, use less jargon, generally provide more evidentiary support, and make weaker novelty claims. Other dimensions, such as assertiveness, qualifiers, and emotional valence, show small or unstable differences.

Extending the analysis to peer review, we find that LLM readability does not exhibit the differential gender effect Hengel 2022 document for their readability measures: peer review improves LLM scores on average, but similarly for male- and female-authored papers. Tests of cumulative exposure likewise fail to replicate, at the aggregate level, the "preemptive adaptation" pattern in which experienced female authors submit cleaner drafts rather than relying on review to close the gap. Patterns resembling that mechanism do, however, reappear in specific dimensions of authorial stance: acknowledgement of limitations and modal verb strength show apparent preemptive softening, while novelty-claim strength instead shows peer review consistently dampening female authors' novelty framing regardless of experience, a pattern that could be read as persistent reviewer resistance rather than rational adaptation. We treat these dimension-specific readings as suggestive rather than conclusive: the same explanations we invoke for the aggregate null (LLM evaluation noise, limited rubric granularity, and the LLM capturing a dimension of writing distinct from review-sensitive readability) apply here as well. With that caveat, the findings raise the possibility that Hengel's mechanism is not entirely absent from LLM-evaluated writing but concentrated in narrower dimensions of stance and hedging rather than overall readability.

The paper does not identify whether these differences reflect selection, training, audience expectations, or differential review pressure, and the LLM-based measures remain subject to measurement error. Even so, the results highlight writing style as a meaningful and understudied margin along which research may be evaluated, circulated, and absorbed within the discipline.

A Rubric

Table 6: LLM Evaluation Rubric

#	Criterion	Description	Scale (1–10)
G1	**Creativity & Hedging**		
1	Modal Verb Strength	Balance of weak (*may*, *might*) vs. strong (*will*, *cannot*) modals	1=only weak; 10=only strong
2	Hedging Frequency & Type	Frequency of single-word qualifiers and larger stance phrases (*it seems that*, *we believe*)	1=continuous hedging; 10=no hedges
3	Qualifier Density	Use of modifiers (*to some extent*, *relatively*) that soften claims	1=extensive qualifiers; 10=none
4	Acknowledgement of Limitations	Explicit mention of caveats or boundary conditions (*within context*, *may not generalize*)	1=numerous limitations; 10=none or implicit only
5	Caution-Signaling Connectors	Use of *however*, *nevertheless*, *on the other hand* to signal complexity	1=frequent; 5=occasional; 10=none
G2	**Assertiveness & Voice**		
6	Assertiveness & Voice	Proportion of unequivocal verbs (*prove*, *confirm*) vs. tentative verbs (*suggest*, *explore*)	1=almost all tentative; 10=almost all assertive
7	Active/Passive Voice Ratio	Ratio of active (*we test*) to passive (*it was tested*) constructions	1=90% passive; 5=50/50; 10=90% active
G3	**Structural Directness**		
8	Sentence Length & Directness	Degree of multi-clausal, convoluted sentences vs. brief, single-clause statements	1=very long; 10=very short
9	Imperative-Form Occurrence	Presence of direct commands (*Apply X*) vs. none or only embedded suggestions	1=no imperatives; 10=dominant
G4	**Authorial Stance & Novelty**		
10	Pronoun Commitment	Use of first-person (*we*, *I*) vs. impersonal constructions (*the authors*)	1=fully impersonal; 10=fully first-person
11	Novelty-Claim Strength	Boldness of originality claims (*first to*, *novel framework*)	1=no novelty claim; 5=hedged; 10=grandiose
12	Jargon/Technicality Density*	Density of undefined field-specific terms vs. accessible language	1=minimal jargon; 10=dense undefined jargon
13	Emotional Valence	Presence of emotionally charged adjectives (*revolutionary*, *urgent*) vs. neutral descriptors	1=none; 10=frequent
G5	**Support & Impact**		
14	Evidence & Citation Usage	How consistently claims are backed by data, statistics, or literature citations	1=none; 10=every claim backed
15	Practical/Impact Orientation	Emphasis on real-world applications, policy, or practice implications	1=none; 5=may inform practice; 10=will transform practice
Standalone			
16	Readability	Precision and ease with which a reader can understand the author's intended meaning	1=difficult; 10=very easy

All criteria are scored 1–10 on surface-level linguistic features only; no inference about author intent is made.

* Scale-flipped (11 − raw score) before computing the G4 composite, so that higher values consistently indicate more accessible language.

B Summary Statistics

Table 7: LLM tonal criteria: summary statistics by gender composition

	All-Male (N = 7,951)	Mixed (N = 853)	All-Female (N = 313)	Full Sample (N = 9,117)

Standalone				
Read	6.70 (1.38)	7.42 (1.25)	7.37 (1.30)	6.79 (1.38)

Notes. Means and standard deviations (in parentheses) of LLM-scored tonal criteria, computed at the article level (AER, ECA, JPE, QJE; one observation per article after deduplication on ArticleID). Criteria scored 1–10. Gender composition is based on *Female_authorship_ratio*: All-Male (ratio = 0), Mixed (0 ¡ ratio ¡ 1), All-Female (ratio = 1). Short labels correspond to G-groups: G1 Creativity & Hedging; G2 Assertiveness & Voice; G3 Structural Directness; G4 Authorial Stance & Novelty; G5 Support & Impact. Readability is a standalone criterion. No significance stars shown; this table is descriptive only.

Table 8 reports article counts by journal and decade for the full Hengel 2022 sample and the four-journal subsample used in this paper. Table 9 reports pairwise correlations among the 16 LLM-scored rubric criteria.

Table 8: Article count, by journal and decade

Decade	*AER*	*ECA*	*JPE*	*QJE*	Total
1950–59		120			120
1960–69		343	184		527
1970–79		660	633	1	1294
1980–89	180	648	562	401	1791
1990–99	476	443	478	409	1806
2000–09	693	519	408	413	2033
2010–15	732	382	181	251	1546
Total	2081	3115	2446	1475	9117

Notes. Included is every article published between January 1950 and December 2015 for which an English abstract was found (i) on journal websites or websites of third party digital libraries or (ii) printed in the article itself. Papers published in the May issue of *AER* (*Papers & Proceedings*) are excluded. Final row and column display total article counts by journal and decade, respectively.

Table 9: Pairwise Pearson Correlations among LLM Tonal Criteria

Read	0.03	0.06	0.09	0.25	-0.01	0.08	0.38	0.75	-0.05	0.22	-0.07	-0.62	0.03	0.23	0.20	1.00

Notes. Pearson correlation coefficients computed at the article level (N = 9,117; AER, ECA, JPE, QJE only; one observation per article). Criteria scored 1–10. Jargon/Technicality Density is shown on its raw scale (not scale-flipped). Group membership (G1–G5): G1 Creativity & Hedging: Modal, Hedge, Qual, AckLim, Caution; G2 Assertiveness & Voice: Assert, ActPass; G3 Structural Directness: Direct, Imperat; G4 Authorial Stance & Novelty: Pronoun, Novelty, Jargon, Emot; G5 Support & Impact: Evid, Pract. Readability is a standalone criterion.

C Table 3: Gender Differences in Readability

This section reports alternative specifications and extensions of Table 1. The five alternative female-authorship specifications used throughout are those described in Section 3.

C.1 Hengel Readability: Alternative Specifications

Notes. Figures represent coefficients on female ratio from 63 separate OLS regressions of individual LLM tonal criteria on the ratio of female authors. Each row is a separate criterion. Criteria belong to groups G4 (Authorial Stance & Novelty), G5 (Support & Impact), and the standalone Readability criterion. † Jargon/Technicality Density is scale-flipped (11 − raw score) so that higher values indicate more accessible language. See companion table for G1–G3. ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

C.4 LLM Individual Criteria: Alternative Specifications

Notes. β_1 from FGLS estimation of the baseline FGLS specification. First column restricts sample to authors' first top-four publication ($t = 1$), second column to their second ($t = 2$), *etc.* Regressions weighted by $1/N_j$. Standard errors (in parentheses) adjusted for two-way clustering (editor and author) and cross-model correlation. Final column estimates from an unweighted population-averaged regression; error correlations specified by an auto-regressive process of order one and standard errors (in parentheses) adjusted for one-way clustering on author. Quality controls denoted by ✓[1] include citation count (asinh), max. T fixed effects (author prominence) and max. t (author seniority); ✓[3] includes citation count (asinh) and max. t, only. The variable "female ratio" defines papers with a strict minority of female authors as male-authored; for papers with 50 percent or more female authors, it is the ratio of female authors on a paper (see the text for more details). ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

Notes. β_1 from FGLS estimation of the baseline FGLS specification. First column restricts sample to authorsfirst top-four publication ($t = 1$), second column to their second ($t = 2$), *etc.* Regressions weighted by $1/N_j$. Standard errors (in parentheses) adjusted for two-way clustering (editor and author) and cross-model correlation. Final column estimates from an unweighted population-averaged regression; error correlations specified by an auto-regressive process of order one and standard errors (in parentheses) adjusted for one-way clustering on author. Quality controls denoted by ✓[1] include citation count (asinh), max. T fixed effects (author prominence) and max. t (author seniority); ✓[3] includes citation count (asinh) and max. t, only. The variable "female ratio" defines papers with a strict minority of female authors as male-authored; for papers with 50 percent or more female authors, it is the ratio of female authors on a paper (see the text for more details). ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

Notes. β_1 from FGLS estimation of the baseline FGLS specification. First column restricts sample to authors' first top-four publication ($t = 1$), second column to their second ($t = 2$), *etc.* Regressions weighted by $1/N_j$. Standard errors (in parentheses) adjusted for two-way clustering (editor and author) and cross-model correlation. Final column estimates from an unweighted population-averaged regression; error correlations specified by an auto-regressive process of order one and standard errors (in parentheses) adjusted for one-way clustering on author. Quality controls denoted by ✓^{1} include citation count (asinh), max. T fixed effects (author prominence) and max. t (author seniority); ✓^{3} includes citation count (asinh) and max. t, only. The variable "female ratio" defines papers with a strict minority of female authors as male-authored; for papers with 50 percent or more female authors, it is the ratio of female authors on a paper (see the text for more details). ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

	(0.28)	(0.21)	(0.20)	(0.25)	(0.34)

Notes. Sample 4,289 observations. Panel one displays magnitude of predicted $R_{jP} - R_{jW}$ (the direct effect of peer review) for women and men over increasing t. Panel two estimates the marginal effect of an article's female ratio ($\beta_1 + \beta_2 \times t$), separately for draft papers and published articles. Figures from FGLS estimation of equation (15), weighted by N_{it} (see the data appendix). Control variables include citation count (asinh), max. T (author prominence) and max. t (author seniority), native speaker and editor and journal-year fixed effects. Standard errors clustered by editor and robust to cross-model correlation in parentheses. ***, ** and * statistically significant at 1%, 5% and 10%, respectively.

G Figure 6: Cumulative Exposure by Criterion

G.1 Remaining (Null) Criteria

The figures below show the cumulative exposure results (analogous to Figure 3) for the criteria that display no differential gender pattern across experience levels: Hedging Frequency and Type, Sentence Length and Directness, Pronoun Commitment, Jargon/Technicality Density, and Evidence and Citation Usage. In each case, peer review effects are roughly constant across t with no meaningful gender differential, consistent with these dimensions reflecting persistent features of writing style rather than responses to external review standards.

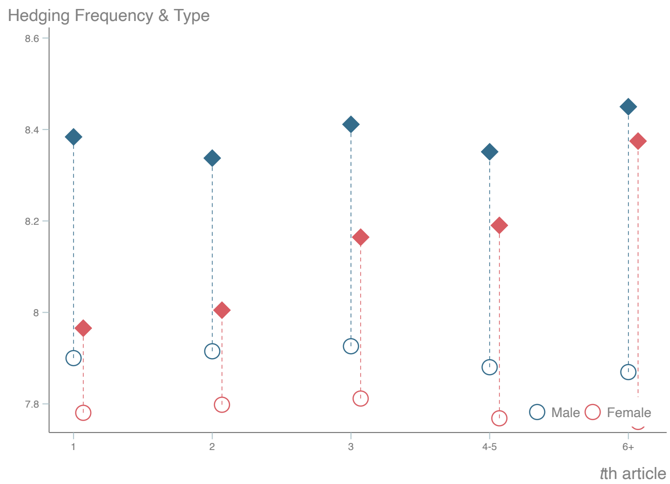

Figure 7: Hedging Frequency & Type of Author's tth paper (draft and final).

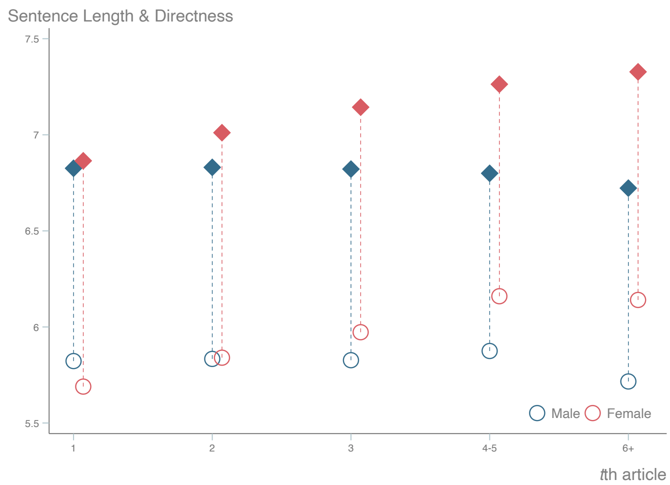

Figure 8: Sentence Length & Directness of Author's tth paper (draft and final).

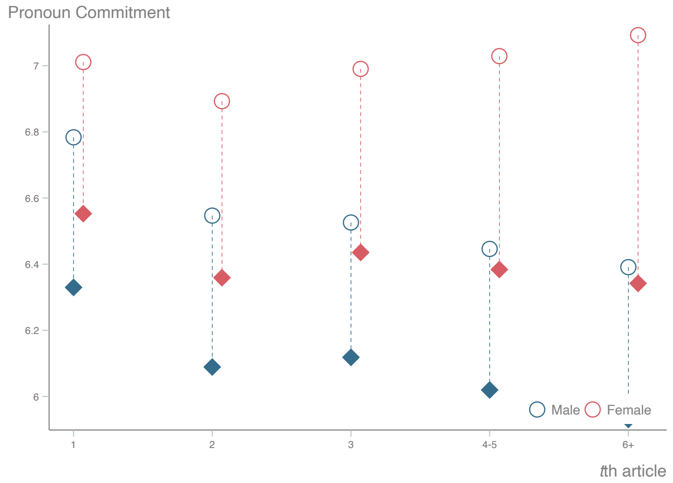

Figure 9: Pronoun Commitment of Author's tth paper (draft and final).

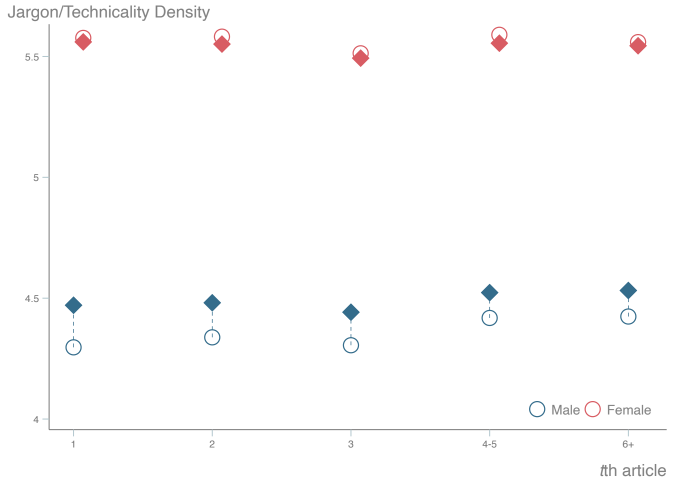

Figure 10: Jargon/Technicality Density of Author's tth paper (draft and final).
